ABSTRACT — The disease of Diabetes is one of the most key and fundamental causes of death rate (mortality) and unhealthiness (morbidity) globally. Renewing act of functional pancreatic islets has been an objective of stem cell biologists since the beginning of 2000. Since then, several investigations have indicated successful creation of glucose-responsive pancreatic beta-cells. Research objective: This paper aimed to investigate the impact of MSC on Streptozotocin (STZ)- induced diabetes in male albino rats to discover its potential therapeutic effect and its possible implementations in human diseases. Methods and materials: Thirty male albino rats (150 – 170 grams) were used in this research study. They were divided into three equal sets: Group I (control), group II (diabetic), and group III (diabetic group treated with MSC). Diabetes was induced by intraperitoneal injection of STZ (60 mg/kg). MSC were injected intravenously into the rat tail vein in the group III and left for two months Glucose and Insulin levels were measured for the three groups at the beginning of the study and after two months. Diabetic group (group II) showed significant higher glucose levels while there was a significant lower insulin levels compared to control group. Group III showed higher insulin and lower glucose level compared to group II. Conclusion: treatment with MSCs. showed significant lower levels of glucose and higher levels of insulin compared to diabetic group.

KEY WORDS: Mesenchymal, Stem Cells, Streptozotocin, diabetic Rat

Introduction
Diabetes is actually a set of diseases described by abnormally high amounts and levels of the sugar glucose in the bloodflow. This extra glucose amount is accountable for most of diabetes problems that encompasses blindness, stroke, neuropathy, kidney failure, heart disease, and amputations (Chen et al; 2004). Type 1 diabetes, also known as juvenile- onset diabetes, typically impacts kids and young people. Diabetes develops when the body's protecting and immune systems see its own cells as outsider and attack and destroy them. Consequently, the islet cells of the pancreas, are destroyed which normally produce insulin. In the absence of insulin, glucose cannot enter the cell and glucose accumulates in the blood (Beati et al., 1997). There is currently no treatment for diabetes. People with type 1 diabetes must take insulin many times a day and test their blood glucose concentration three to four times a day throughout their full lives. Continuous monitoring is significant because patients who keep their blood glucose concentrations as close to normal as possible can significantly reduce many of the complications of diabetes, such as retinopathy (a disease of the small blood vessels of the eye which can lead to blindness) and heart disease, that tend to develop over time(Bonner et al., 2000). Over the past several years, doctors have attempted to cure diabetes by injecting patients with pancreatic islet cells—the cells of the pancreas that Secrete insulin and other hormones. However, the requirement for steroid immunosuppressant therapy to prevent rejection of the cells increases the metabolic demand on insulin-producing cells and eventually they may exhaust their capacity to produce insulin. The deleterious effect of steroids is greater for islet cell transplants than for whole-organ transplants (Itken et al., 2001). 2006).Researches have shifted their attention to adult stem cell that appear to be precursors to islet cells and embryonic stem cells that produce insulin (Assady et al., 2001). (Surprisingly, the administration of adult stem cell in several experimental diseases has showed to improve its clinical outcome and more over amelioration of tissue architecture. The mechanism of action that leads to this improvement is not well defined, whether it is due to fusion of dying cells with MSC, differentiation of MSC to other cell types or through a paracrine action, where several bioactive factors contribute to the main mechanism of action suggested by Zuk et al. All tissues per se have the capacity of homeostasis maintenance. However, after injury this process is somehow disturbed by inflammation or by extracellular matrix disruption, not allowing proper stem cell action. Thus, in a way to assist the repair process several works have focused on the administration of exogenous stem cells (Gabby et al. that can be found in almost all postnatal organs and tissues (Porada et al., 2006). MSCs are most frequently isolated from bone marrow but can generally be derived from any organ (Da silva et al. 2006). Depending on their intended purpose, experimental or therapeutic use, MSCs can be isolated from adipose tissue, umbilical cord blood, compact bone, and other tissues (Ettla et al., 2004). The main functional characteristics of MSCs are their immune-
modulatory ability, for self-renewal, and differentiation into tissues of mesodermal origin (Addi et al., 2008). There is a possible therapeutic effect of MSCs in diabetes suggested by their capacity to generate insulin-producing cells (IPC) (Nautta and Febbe; 2007). These IPCs express multiple genes related to the development or function of pancreatic beta cells, including high expression of insulin (Volarevic et al., 2010) and were able to release insulin in a glucose-dependent manner that led to amelioration of diabetic conditions in streptozotocin (STZ)-treated rats (Xie et al., 2009). Several lines of evidence suggest that in vivo hyperglycemia is an important factor for bone marrow-derived MSCs differentiation into IPCs capable of normalizing hyperglycemia in diabetic rats, including those with chronic hyperglycemia (Tang et al., 2004).

Material and methods
Thirty white male albino rats aged one month (150-170 grams) were included in the present study. They were obtained from Ophthalmology Institute and were housed in wire mesh cages at room temperature and maintained on normal chow and had free access to water. The rats were divided into three groups, each group ten rats

Group 1: Control group.
Group 2: Diabetic group using Streptozotosin (S.T.Z.).
Group 3: Diabetic group treated with MSC

Diabetes was induced by injection of STZ at a dose of 60 mg./Kg/day (Fujita et al., 2005). M.S.C. were injected once intravenously in the rat tail. Blood samples were taken at the beginning and at the end of experimental period for determination of glucose level and insulin level. The glucose and insulin levels were measured by spectrophotometry and E.L.I.S.A. methods respectively.

Preparation of BM-derived MSC
Rat diabetic models were made to test in vivo function of differentiated MSCs. Rat MSCs were isolated from bone marrow of Wistar rats and cultured. Passaged MSCs were induced to differentiate into islet-like cells under following conditions: pre-induction with L-DMEM including 10 mmol/L nicotinamide + 1 mmol/L beta-mercaptoethanol+200 mL/L fetal calf serum (FSC) for 24 hrs, followed by induction with serum free H-DMEM solution including 10 mmol/L nicotinamide+1 mmol/L, beta-mercaptoethanol for 10 hrs. Differentiated cells were observed under inverse microscopy, and identified by expressing a gene called PDX-1, which encodes a protein that initiates transcription from the insulin gene. These genes, called cell markers, are useful in identifying particular cell types. insulin and nestin expressed in differentiated cells were detected with immunocytochemistry. Insulin excreted from differentiated cells was tested with radioimmunoassay. Groups II subjected to STZ showed significant higher levels for glucose and lower levels for insulin when compared with the control group (P < 0.05). Group III which received M.S.C. as a treatment showed a significant improvement in the levels of glucose and insulin in comparison to the levels without treatment (P < 0.05).
Results

Table 1 showed serum levels for glucose and insulin in all studied groups

Groups II subjected to STZ showed significant higher levels for glucose and lower levels for insulin when compared with the control group (P < 0.05). Group III which received M.S.C. as a treatment showed a significant improvement in the levels of glucose and insulin in comparison to the levels without treatment (P < 0.05).

Discussion

Type 1 diabetes mellitus (T1D) is caused by an immune mediated destruction of the insulin producing β cells in the pancreas. β Cell destruction is irreversible and despite intensive insulin therapy the condition is connected with development of late diabetic complications and increased mortality (Borch and Jhonson, 1989). In developing a potential therapy for patients with diabetes, researchers hope to develop a system that meets several criteria. Ideally, stem cells were able to multiply in culture and reproduce themselves exactly. That is, the cells should be self-renewing. Stem cells should also be able to differentiate in vivo to produce the desired kind of cells For diabetes therapy, it was not clear whether it will be desirable to produce only beta cells—the islet cells that manufacture insulin—or whether other types of pancreatic islet cells are also necessary. Studies by (Soria et al., 2000), indicated that isolated beta cells—those cultured in the absence of the other types of islet cells—are less responsive to changes in glucose concentration than intact islet clusters made up of all islet cell types. Islet cell clusters typically respond to higher-than-normal concentrations of glucose by releasing insulin in two phases: a quick release of high concentrations of insulin and a slower release of lower concentrations of insulin. In this manner the beta cells can fine-tune their response to glucose. As multipolar nerve cells known as ganglion cells are responsible for activation of beta cells to secrete insulin (Schuldiner et al., 2000). The objective of the present study was to study the potential therapeutic effect of M.S.C. injection in STZ induced diabetes in rats. Rats were divided into 3 equal groups,1st one was the control group,2nd group received Steptozotocin to induce diabetes and the 3rd one received both Steptozotocin and MSCs. Results show a significant higher levels of glucose in group 2 (diabetic group) compared to control group (P >0.005), while the insulin level showed significant lower level in the diabetic group (P < 0.005), when compared with the same group. Group III which was treated with the MSCs, showed significant lower level of glucose in compared to the diabetic group with significant higher level of insulin in comparison to diabetic group. Improvement of insulin secretion may be due to MSCs. These results agreed with the results of (Rottoli et al., 2004). They stated that the stem cells migrate to the site of damage and undergo differentiation and promote structural and functional repair and help to cure diabetes and thus restore the normal insulin level in the body.
Histological results

New islets of Langerhans reappear again after stem cell therapy in 7 rats. No islets of Langerhans were detected in 2 of the rats. It is important to denote that one of the rats who received stem cells showed malignant transformation of pancreas. The results of the present study agree with (Chen et al., 2004) whom stated that the Islet-like functional cells differentiated from marrow.

Functional areas of Islets of Langerhans appear again in pancreatic tail after stem cell therapy.

Histological section denote malignant transformation of pancreas of one rat

Mesenchymal stem cells, may be a new procedure for clinical diabetes stem -cell therapy, as they can control blood glucose level in the diabetic rats, by islet differentiation. The major problem in dealing with these cells is maintaining the delicate balance between growth and differentiation. Cells that proliferate well do not produce insulin efficiently, and those that do produce insulin do not proliferate well. According to the researchers, the major issue is developing the technology to be able to grow large numbers of these cells that will reproduce and produce normal amounts of insulin (Levine; 2001). The discovery of the methods to isolate and grow human embryonic stem cells renewed the hopes of doctors, researchers, and diabetes patients and their families that a cure for type 1 diabetes, and perhaps type 2 diabetes as well, may be within striking distance. In theory, embryonic stem cells could be cultivated and coaxed into developing into the insulin-producing islet cells of the pancreas. With a ready supply of cultured stem cells at hand, the theory is that a line of embryonic stem cells could be grown up as needed for anyone requiring a transplant. It is important to denote that one of the rats who receives stem cells show malignant transformation of pancreas so we cannot say that stem cell therapy is completely safe in humans.
